# From Loop Space Mechanics to Nonabelian Strings

Urs Schreiber

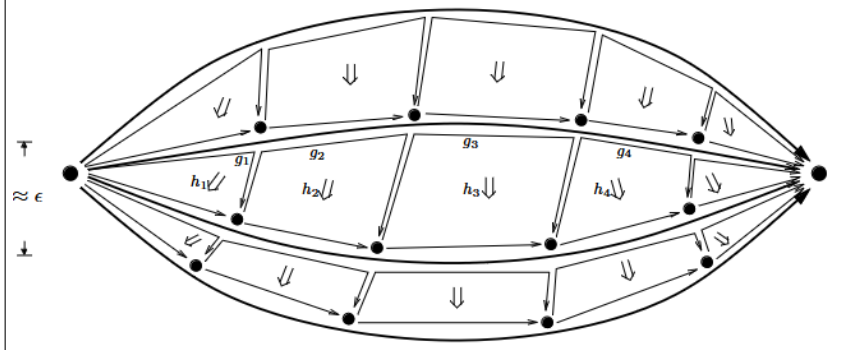

Lifting supersymmetric quantum mechanics to loop space yields the superstring. A particle charged under a fiber bundle thereby turns into a string charged under a 2-bundle, or gerbe. This stringification is nothing but categorification. We look at supersymmetric quantum mechanics on loop space and demonstrate how deformations here give rise to superstring background fields and boundary states, and, when generalized, to local nonabelian connections on loop space. In order to get a global description of these connections we introduce and [study](#) [categorified global holonomy in the form of 2-bundles with 2-holonomy](#). We show [how these relate to nonabelian gerbes and go beyond by obtaining global nonabelian surface holonomy](#), thus providing a class of action functionals for nonabelian strings. The examination of the differential formulation, which is adapted to the study of nonabelian p-form gauge theories, gives rise to generalized nonabelian Deligne hypercohomology. The (possible) relation of this to strings in Kalb-Ramond backgrounds, to M2/M5-brane systems, to spinning strings and to the derived category description of D-branes is discussed. In particular, there is a 2-group related to the String-group which should be the right structure 2-group for the global description of spinning strings.

## 11.4 2-Holonomy in Terms of Local p-Forms

In this subsection the proof of the central proposition [11.2](#) (p. [260](#)) is sketched in a way that is supposed to clearly point out the underlying mechanisms in a concise way. Several technicalities that these proofs rely on are then discussed in detail in [§11.5](#) (p.[268](#)).

### 11.4.1 Definition on Single Overlaps

Consider any bigon  $\Sigma$  in a patch  $U_i$ , i.e. a 2-morphism in  $\mathcal{P}_2(U_i)$  (def. [11.13](#)), and consider a local 2-holonomy functor  $\text{hol}_i: \mathcal{P}_2(U_i) \rightarrow \mathcal{G}$  (def. [11.15](#)). Since  $\text{hol}_i$  is a functor, the 2-group 2-morphism which it associates to  $\Sigma$  can be computed by dividing  $\Sigma$  into many small sub-bigons, evaluating  $\text{hol}_i$  on each of these and composing the result in  $\mathcal{G}$ . This is illustrated in the following sketchy figure.

This was motivated from high energy physics (HEP).

## Motivations and Perspectives.

- *in classical HEP*

classical background connection (“gauge field”) is the physical datum to be understood  
*probed* by paths (“Wilson loops”)

or surfaces (“Wilson surfaces”)

that are chosen as prescribed observables

Theorem: Connections are fully characterized by their path holonomy.(e.g. [SW09])

Analogously for 2-connections and 2-holonomy. (e.g. [SW13])

- *in quantum HEP*

one imagines “averaging” (path integral) over all background fields

and now the averaged parallel transport characterizes the path!

cf. knot invariants via Chern-Simons theory

- *in data science* (I gather) it is currently

the background connection that is chosen by hand

in fact to be the most trivial/tautological one,

and information about the path/surface to be extracted

In HEP instead of using the free Lie algebra, one would use  $\mathfrak{u}(N)$  for arbitrary/large  $N$ .

In HEP one cares also about connections **on non-trivial bundles**: “instantons”, “solitons”.

This is relevant when the target space  $X$  of the paths/surfaces  $[0, 1]^n \rightarrow X$  is no longer just Euclidean space  $\mathbb{R}^d$ .

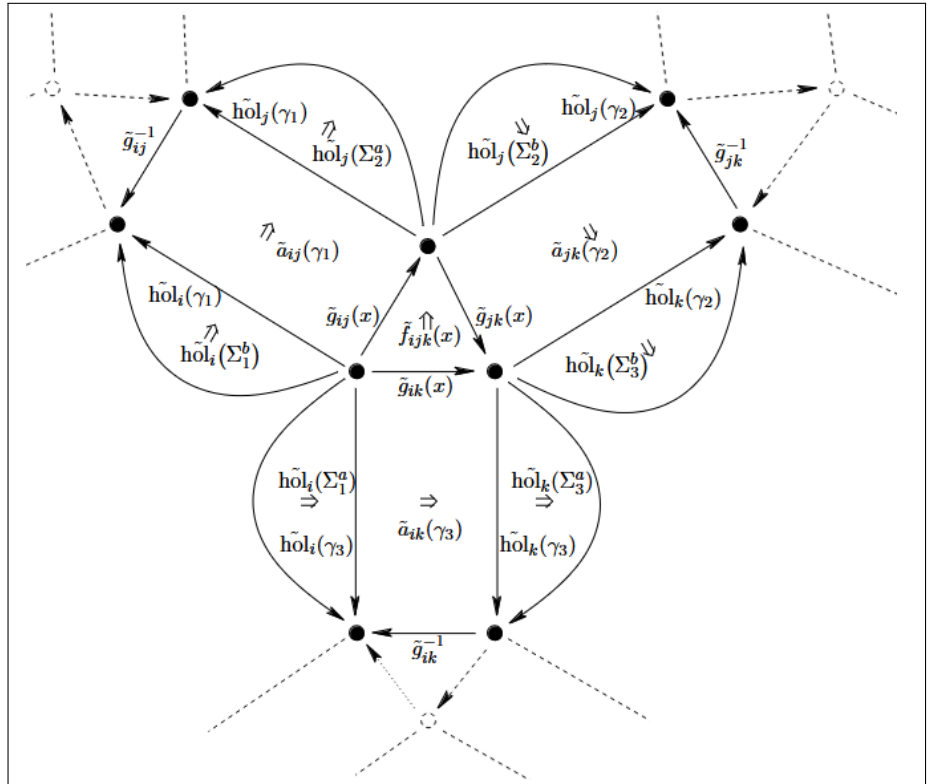

In data science this case may remain underappreciated, but consider for instance:

$$X := \left\{ \begin{array}{l} \text{points on earth} \\ \& \text{wind direction} \end{array} \right\}$$

$$= S(TS^2) \simeq \mathbb{R}P^3 \simeq S^3/\mathbb{Z}_2$$

In this case the local surface holonomy needs to be accompanied by  
*Čech cocycle data*

Indicated on the right,  
 now to be explained.

The issue is:

On a general manifold  $X$   
connection data in general only exists *locally*  
namely on an *open cover*

$$C := \coprod_{i \in I} U_i \xrightarrow{(\iota_i)_{i \in I}} X \quad \text{for} \quad \left\{ \mathbb{R}^n \simeq U_i \xrightarrow[\text{opn}]{\iota_i} X \right\}_{i \in I}$$

and so in order to continue parallel transport  
from one chart  $U_i$  to the next  $U_j$   
one needs a *gauge transformation*  
relating the connection on  $U_i$  with that on  $U_j$   
where they overlap, on  $U_{ij} := U_i \cap U_j$

and this must be consistent:

gauge transforming from  $U_i$  to  $U_j$  and from there to  $U_k$   
must be the same as transforming directly from  $U_i$  to  $U_k$

or at least these two gauge transformations  
must be *gauge-of-gauge* equivalent on  $U_{ijk} := U_i \cap U_j \cap U_k$

and so on.

Such data subject to such consistency conditions  
is called *Čech cocycle data*.

**Labelling surface elements by strict 2-groupoids** coming from crossed modules of groups means:

Consider a group homomorphism  $H \xrightarrow{t} G$

labelling surface elements with pairs  $g \in G$  and  $h \in H$  like this:

$$\begin{array}{c} g \\ \curvearrowright \\ * \quad \Downarrow h \quad * \\ \curvearrowleft \\ t(h) \cdot g \end{array} \equiv \begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow h \quad * \\ \curvearrowleft \\ t(h) \end{array} \xrightarrow{g} *$$

such that

$$\begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow h_1 \quad * \\ \curvearrowleft \\ t(h_1) \end{array} \begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow h_2 \quad * \\ \curvearrowleft \\ t(h_2) \end{array} = \begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow h_1 \cdot h_2 \quad * \\ \curvearrowleft \\ t(h_1 h_2) \end{array}$$

and

$$\begin{array}{c} e \\ \curvearrowright \\ * \xrightarrow{t(h)} * \\ \Downarrow h \\ \Downarrow h' \\ \curvearrowleft \\ t(h'h) \end{array} = \begin{array}{c} e \\ \curvearrowright \\ * \xrightarrow{e} * \\ \Downarrow h' \\ \curvearrowleft \\ t(h') \end{array} \begin{array}{c} e \\ \curvearrowright \\ * \xrightarrow{t(h)} * \\ \Downarrow h \\ \curvearrowleft \\ t(h) \end{array} = \begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow h'h \quad * \\ \curvearrowleft \\ t(h'h) \end{array}$$

and such that the order of horizontal/vertical composition doesn't matter. This implies that

$$* \xrightarrow{g} * \begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow h \quad * \\ \curvearrowleft \\ t(h) \end{array} \xrightarrow{g^{-1}} * = \begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow \alpha(g)(h) \quad * \\ \curvearrowleft \\ g \cdot t(h) \cdot g^{-1} \end{array}$$

for some group homomorphism  $\alpha : G \longrightarrow \text{Aut}(H)$  such that  $t(\alpha(g)(h)) = g \cdot t(h) \cdot g^{-1}$  and that

$$* \xrightarrow{t(h)} * \begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow h' \quad * \\ \curvearrowleft \\ t(h') \end{array} \xrightarrow{t(h)^{-1}} * = \begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow h \quad * \\ \curvearrowleft \\ t(h) \end{array} \begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow h' \quad * \\ \curvearrowleft \\ t(h') \end{array} \xrightarrow{t(h)^{-1}} * = \begin{array}{c} e \\ \curvearrowright \\ * \quad \Downarrow h \cdot h' \cdot h^{-1} \quad * \\ \curvearrowleft \\ t(h \cdot h' \cdot h^{-1}) \end{array}$$

hence that  $\alpha(t(h))(h') = h \cdot h' \cdot h^{-1}$

The boxed items make a **crossed module of groups**.

First consider the ordinary case of  
**Parallel 1-Transport along paths.**

**Figure 11: Global (1-)holonomy in terms of (1-)torsor (1-)morphisms.** The functor  $\text{hol}$  associates torsor morphisms between fibers to paths in the base manifold. Using trivialisations  $t_i$  on patches  $U_i$  these torsor morphisms can be identified with elements of the structure group. The step  $t_i^{-1} \circ t_j$  from one trivialization to another one on double overlaps  $U_{ij}$  gives rise to multiplication by the transition function  $g_{ij}$ .

To generalize this to  
**2-Transport along surfaces.**

**12.4.2.2 Surface Holonomy in Terms of Local Trivializations.** Now consider the application of  $\text{hol}$  to any 2-morphism  $[\Sigma] \in \mathcal{P}_2(M)$  that does not necessarily sit in a single patch.

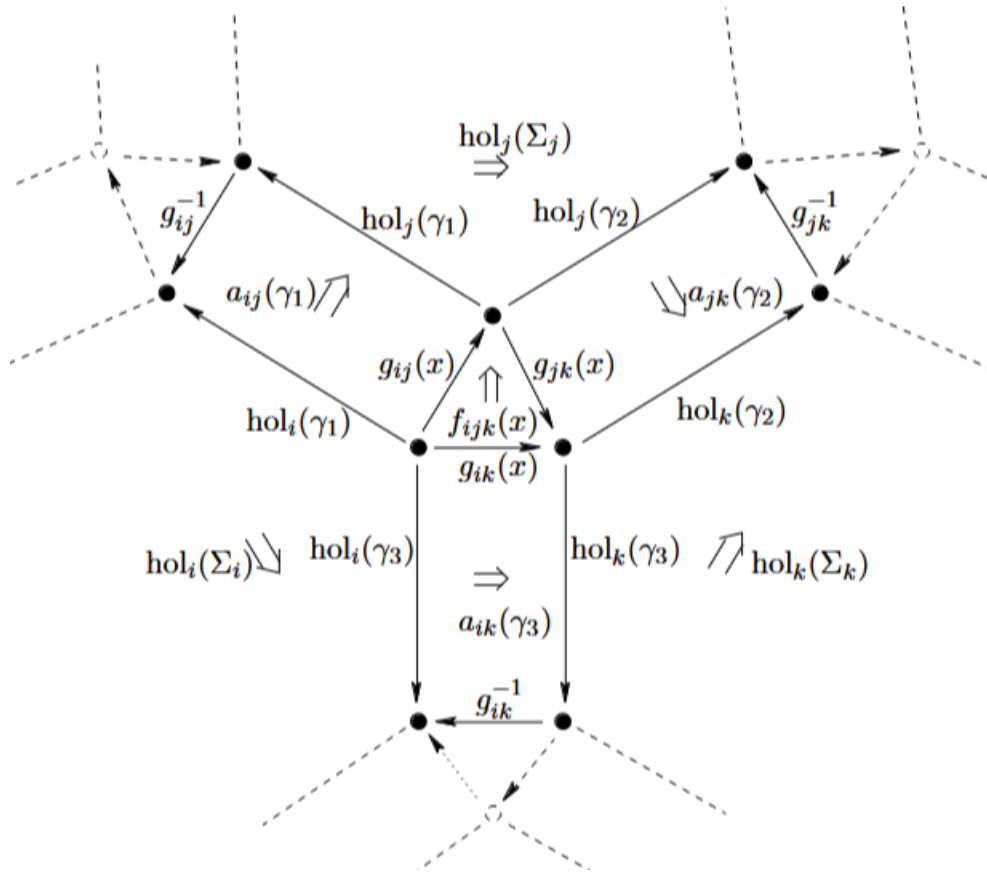

We can decompose  $[\Sigma]$  into several 2-morphisms that all do sit inside a single patch of the covering. Their images under  $\text{hol}$  can be regarded as the “bottom” (leftmost surface) of the tincan diagram (12.11). Since this tincan diagram 2-commutes, we can replace each  $\text{hol}(\Sigma_i)$  by the the respective tincan with its leftmost surface cut out. This is shown in the following figure.

Now

and hence the 2-holonomy is given by

**Consistency conditions.** For this 2-homology not to depend on the choice of where to insert the gauge transformations, the following conditions must be met:

One comes from the condition that degenerate surfaces do not contribute. Consider moving  $x \in U_{ijk}$  to  $x' \in U_{ijk}$  by extending all of  $\gamma_1, \gamma_2, \gamma_3$  by the *same* path  $x \rightarrow x'$ .

This removes  $f_{ijk}(x)$  in the above diagram and replaces it by a diagram of the above form around  $x'$  but with all  $\Sigma_i$  vanishing. Since this must not contribute, this diagram has to equal the 2-morphism  $f_{ijk}(x)$  that was replaced. In other words, the  $a_{ij}$  must be such that the following diagram 2-commutes:

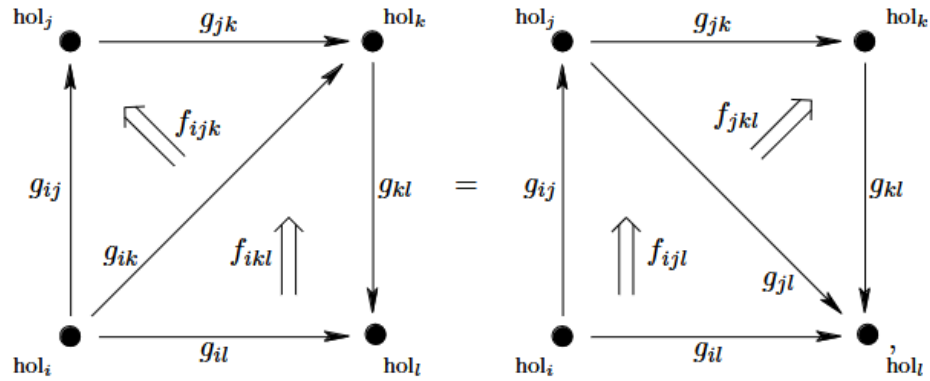

The other consistency condition is obtained by considering vertices at which more than three edges meet. Whenever this is the case, we can insert constant paths until only trivalent vertices are left. But these constant paths can be inserted in more than one way. For a 4-valent vertex this is indicated by the following figure.

Here  $\gamma_0$  denotes a constant path, which has been drawn with a spatial extension just for convenience. It is a well known theorem (see for instance [84]) that all triangulations can be obtained from any given one by a series of moves of two types, one of which is the one from one of the lower two pictures to the other. The other is the “bubble move” which was called the “left and right unit law” in §11.2.4 (p.251).

Invariance of hol under this move is expressed by the equation

which is equivalent to the 2-commutativity of this tetrahedron:

This is the tetrahedron transition law on quadruple overlaps known from equation (11.15) (p. 260) and from §11.2.4 (p. 251).

This is the nonabelian Čech 2-cocycle condition for the **principal 2-bundle** underlying the 2-connection.
